ABSTRACT

Cytokinesis, the final step of cell division, is a great example of robust cell shape regulation. A wide variety of cells ranging from the unicellular *Dictyostelium* to human cells in tissues proceed through highly similar, stereotypical cell shape changes during cell division. Typically, cells first round up forming a cleavage furrow in the middle, which constricts resulting in the formation of two daughter cells. Tight control of cytokinesis is essential for proper segregation of genetic and cellular materials, and its failure is deleterious to cell viability. Thus, biological systems have developed elaborate mechanisms to ensure high fidelity of cytokinesis, including the existence of multiple biochemical and mechanical pathways regulated through feedback. In this review, we focus on the built-in redundancy of the cytoskeletal machinery that allows cells to divide successfully in a variety of biological and mechanical contexts. Using *Dictyostelium* cytokinesis as an example, we demonstrate that the crosstalk between biochemical and mechanical signaling through feedback ensures correct assembly and function of the cell division machinery.

1. Introduction

Cell division is essential for cell survival and proliferation. Cells must interface with diverse chemical and mechanical stimuli to

ensure successful division in a variety of cellular and tissue contexts. For example, a stem cell needs to decide if and how to divide asymmetrically while a dividing epithelial cell must choose the right division plane to maintain the tissue architecture. Thus, it makes sense that biological systems have developed intricate and robust mechanisms for cytokinesis, the final stage of cell division where the daughter cells separate. Thus, the father of modern cytokinesis research, Ray Rappaport, aptly said “*When I began working on cytokinesis, I thought I was tinkering with a beautifully made Swiss watch, but what I was really working on was an old Maine fishing boat engine: overbuilt, inefficient, never-failed, and repaired by simple measures.*” [1]. The reliability of the boat engine is an essential

attribute for the fisherman dependent on it to make a living. Similarly, numerous feedback loops as well as crosstalk between several biochemical and mechanical pathways ensure robust cytokinesis [2–4].

Cells can be thought of as machines that use chemical and mechanical inputs to make decisions on cell proliferation and fate. For the early forms of life, it is likely that their behavior was largely governed by physical cues such as confinement, pressure and temperature, and cellular systems have since evolved to respond to their environment. For example, barophilic organisms living deep under the sea use different machinery to divide from brain cells in an extremely soft environment. Even within metazoans, though core cytokinesis machinery exists, it is regulated differently in various cell types depending on functionality and context. Thus, in addition to biochemical signaling pathways, the impact of mechanical forces on cell behavior must also be evaluated. This is especially important for cytokinesis, which is largely a physical process involving cell shape changes through cellular contractility. In this review, we will discuss the mechanisms for multi-level regulation of the cytokinesis machinery, using *Dictyostelium* cytokinesis as an example. Its genetic homology and mechanical similarity to many mammalian cells, as well as its amenability for genetic, biochemical and mechanical perturbations, make the social amoeba *Dictyostelium discoideum* an excellent model for cytokinesis research. Aspects of biochemical and mechanical feedback regulation of cytokinesis and cell shape changes observed in *Dictyostelium* have also been demonstrated in other types of cell processes, such as embryonic development, myoblast fusion, immune cell maturation, and cell entosis [5–8].

2. Molecular and physical framework for cytokinesis

The network of actin and associated proteins beneath the cell surface constitutes the cell cortex, and gives the cell its shape and mechanical properties. The cortex is a highly dynamic organelle that undergoes constant remodeling as the cell changes shape during cytokinesis. A diverse array of actin crosslinkers confers structural and mechanical properties to the cortex by interacting dynamically with the actin filament framework, while the myosin motors generate contractile forces in the cortex. Myosin II and many crosslinkers accumulate in the equatorial region or cleavage furrow of a dividing cell, promoting local contractility [4,9] (Fig. 1A). However, cytokinesis is sufficiently robust that it can proceed without myosin II [10], guided by the Laplace pressures that arise from the viscoelastic properties of the cortex and cytoplasm and from the local curvature of the cell surface [3,11,12]. Many cleavage furrow-enriched proteins including myosin II and cortexillin I, an actin crosslinker, also accumulate to sites of applied mechanical stress such as by micropipette aspiration or agarose overlay in a stress-dependent manner (Fig. 1A, B) [13–15]. Both myosin II and cortexillin I show cooperative accumulation kinetics (Fig. 1C), the mechanisms for which are discussed later. Further, the cortexillin I-binding regulatory protein IQGAP2 also shows mechanosensitive accumulation [13].

In addition to the actin cytoskeleton, microtubules and their associated proteins are essential for ensuring correct spatial and temporal positioning of the cytokinesis machinery. The mitotic spindle provides the necessary framework for the initial symmetry breaking and assembly of the cytokinesis apparatus [16–19]. Cues from both spindle and astral microtubules provide spatial regulation, while signaling pathways involving spindle-associated proteins regulate the timing of cytokinesis [2,19,20]. Many proteins that control the cell cycle also regulate cytokinesis. For example, Cdk1 inhibition upon anaphase onset triggers a signaling cascade through RhoA, resulting in major cytoskeletal reorganization

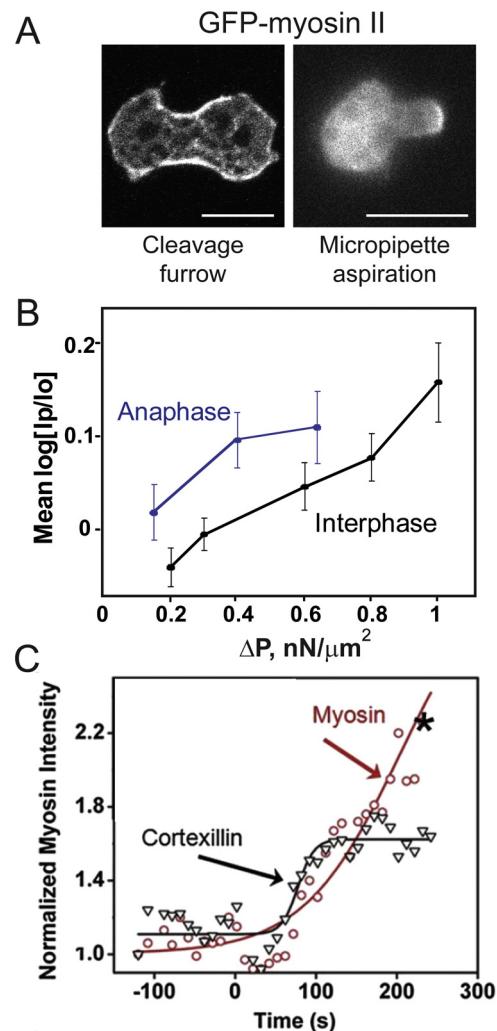

Fig. 1. Myosin II localization is guided by mechanical stress. (A) Myosin II is enriched at the cleavage furrow of a dividing cell and at the aspirated tip during micropipette aspiration (MPA). (B) Myosin II enrichment during MPA depends on the applied pressure. Anaphase *Dictyostelium* cells are more mechanoresponsive than interphase cells. (C) Myosin II and cortexillin I show cooperative accumulation kinetics during MPA.

associated with cytokinesis [21,22]. Members of the chromosome passenger complex (CPC) localize to the cleavage furrow cortex from the mitotic spindle, and modulate shape change during cytokinesis [13,23,24]. Though signals from the mitotic spindle define contractility at the cleavage furrow, cellular contractility can also affect the localization of spindle signaling proteins through feedback (Fig. 2). For example, the mitotic kinesin-like protein (MKLP)-homolog kif12 and the CPC protein INCENP both accumulate to sites of high mechanical stress in *Dictyostelium* [13].

Once we have assembled a parts list for cytokinesis, the question then becomes how do the various cellular modules communicate and collaborate to ensure cytokinesis proceeds with high fidelity. The signaling pathways regulating cytokinesis in different organisms have been extensively studied [2,16,25–27]. However, mechanical signaling must also be integrated with these pathways to completely understand cytokinesis regulation.

3. Mechanics of cytokinesis

Actin crosslinkers and the motor protein myosin II collectively bear the force (mechanical load) in the cortex. By altering the

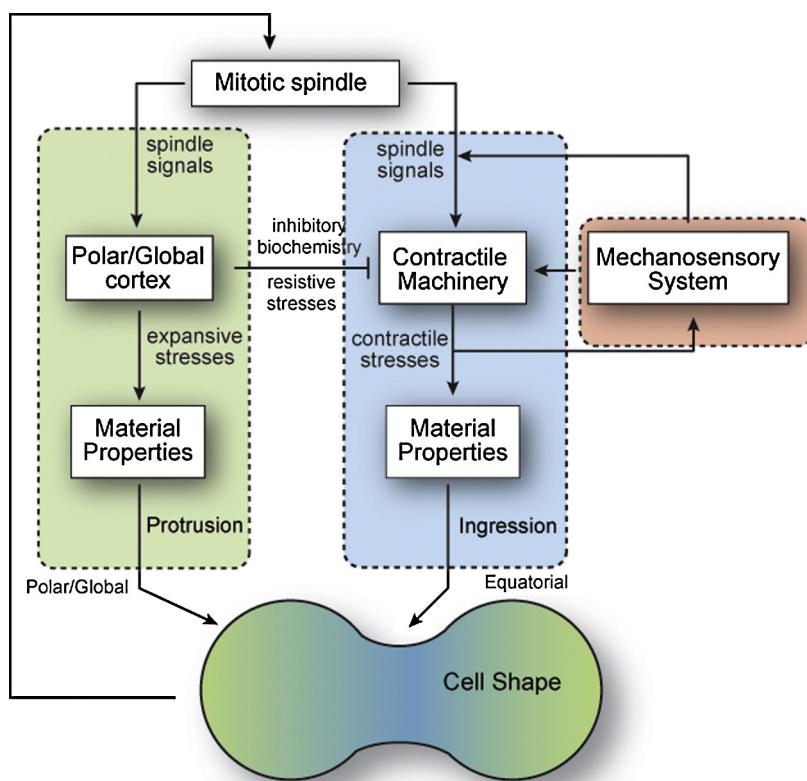

Fig. 2. A combination of biochemical and mechanical cues from the mitotic spindle, and polar and equatorial cortices guide cytokinesis progression. The contractile machinery, comprising of myosin II and cortexillin I, is recruited at the cleavage furrow and is regulated by a mechanosensory system. Polar actin crosslinkers define global mechanics, inhibiting contractility and promoting protrusions in the polar cortex.

composition of the cortex, the physical properties of this composite material and protein behavior are affected [14]. Therefore, asymmetric localization of polar and equatorial crosslinkers during cytokinesis results in a mechanical gradient, where the furrow is less deformable than the poles [9]. Further, myosin II and the equatorial crosslinking protein cortexillin I are mechanoresponsive and accumulate to regions of high stress [13–15,28]. Thus, the higher tension at the furrow helps stabilize the cleavage furrow localization of these proteins. Consistently, the cleavage furrow immobile fractions for cleavage furrow proteins, including myosin II, cortexillin I and IQGAP2, are significantly higher than those in the interphase cortex [29]. Importantly, the immobilization of cleavage furrow proteins during cytokinesis is due to changes in network properties and mechanical forces at the furrow, and is independent of many genetic perturbations [29]. In contrast, the polar crosslinkers, with faster, cytokinesis-independent protein dynamics, contribute to resistive stresses at the poles and modulate cortical tension [9,30,31]. Thus, spatial segregation of permissive and inhibitory signals helps stabilize the furrow positioning and ingestion (Fig. 2).

The mechanoresponsiveness of the cell cortex and its components is dependent on how forces are shared between myosin II and actin crosslinkers. For example, in the absence of myosin II, certain crosslinkers such as α -actinin become more responsive to mechanical deformations. Moreover, mechanosensitive accumulation of myosin II is greater in mutants depleted of the polar crosslinker dynacortin or the small GTPase racE, which affects several polar crosslinkers [14]. Consistently, myosin II can accumulate to aspirated sites at much lower pressures in mitotic cells compared to interphase cells [14,28]. From mechanical studies, a general pattern emerges: whereas loss of cleavage furrow crosslinker cortexillin I and its regulator IQGAP2 leads to

diminished myosin II mechanosensitive accumulation, loss of any of the polar crosslinkers leads to increased myosin II mechanosensitive accumulation. This basic trend reflects the force-sharing between the polar crosslinkers and myosin II as well as the cooperative interactions between myosin II and cortexillin I. This paradigm will be expanded upon in the subsequent sections.

4. Myosin II mechanochemistry and cellular contractility

As myosin II is the major driver of furrow contractility, a detailed evaluation of the molecular mechanisms giving rise to myosin II's mechanoresponsiveness and its interactions with other cortical proteins is necessary for understanding how different components discussed above work together to regulate cytokinesis. Myosin II can assemble into bipolar thick filaments, which generate contractile forces by simultaneously pulling on several actin filaments. Both myosin II–actin binding and thick filament dynamics are force-dependent, and control myosin II's mechanoresponsiveness and cellular contractility.

A functional myosin II monomer is a hexamer comprised of two myosin heavy chains containing the motor and BTF assembly domains, two essential light chains and two regulatory light chains. Myosin II filament assembly and contractility are highly regulated by phosphorylation of both the heavy chain and the regulatory light chain [32,33]. Phosphorylation of the regulatory light chain is controlled by the myosin light chain kinase (MLCK) and Rho-associated protein kinase (ROCK, in mammals; not found in *Dictyostelium*), and activates myosin II [34]. Phosphorylation of the myosin heavy chain regulates its ability to get incorporated into BTFs. Heavy chain dephosphorylation by PP2A promotes BTF assembly while myosin heavy chain kinases inhibit BTF formation [35,36]. The BTF assembly and disassembly dynamics are required for

mechanosensitive remodeling of the cell cortex, as constitutively assembled or unassembled myosin II mutants do not accumulate to sites of high stress [15]. Hence, the regulation by phosphorylation sets the threshold for assembly, allowing mechanical stress to trigger the cooperativity of myosin motor heads (discussed in the next section) thereby dictating the precise location of where that BTF assembly will occur and on which actin filaments it will assemble [37,38].

The enrichment of myosin II BTFs results in increased cellular contractility in regions of high stress. Consequently, the cell retracts from the aspirated site once myosin II is maximally recruited during micropipette aspiration [14,28]. As the cell retracts, the cortex becomes less strained and myosin II unbinds from the cortex. In some mutants, like *racE* cells where myosin II is highly mechanoresponsive, myosin II accumulation and cellular retraction show out-of-phase oscillatory behavior [14]. Myosin II can also localize asymmetrically during early cytokinesis when the spindle is not centered to correct for shape asymmetries. Myosin II gets enriched furthest from the spindle and redistributes as the spindle elongates [28]. Myosin II induced contractility is also critical for tumor invasion and metastasis, where highly deformable and contractile cells have a higher metastatic potential [6,39]. Thus, modulation of the contractile machinery is an important therapeutic strategy for cancer prevention and cure.

5. Cooperativity between myosin II and actin crosslinkers

Though myosin II is the force generating enzyme, actin crosslinkers are necessary for propagation of forces within the cortex. Both myosin II and cortexillin I accumulate at the cleavage furrow, and exhibit cooperative accumulation under micropipette aspiration (Fig. 1C), where the deletion of one disrupts the stress-dependent accumulation of the other [15]. Their synchronous accumulation suggests cooperative interactions between myosin II and cortexillin I.

Myosin II undergoes an ATP hydrolysis-dependent power stroke, during which it takes an 8 nm step along the actin filament [40,41]. Myosin II binding to the actin filament causes localized conformational changes in the filament, resulting in strain energy for the filament, which promotes the binding of additional myosin heads nearby. The force generated during the myosin II power stroke creates tension in crosslinked actin filaments, and this tension results in an increased binding lifetime of myosin II by locking it in the isometric state [42], which is also the cooperative binding state [37]. Coarse-grained Monte Carlo simulations for force-dependent myosin II binding can recapitulate the homo-cooperativity between myosin heads *in silico* [37], which has also been demonstrated *in vitro*. Microscopy showed that myosin II motors bind in clusters to actin filaments in a manner dependent on the actin conformation [43] or on the myosin motor's nucleotide state (ATP- or transition state analog-bound, but not ADP-bound) [44]. Intriguingly, a mutant myosin S1, which populates the transition state (also the cooperative binding state), localized to specific populations of actin in the cell, including the actin in the cleavage furrow [45]. Further, in a reconstituted muscle myosin II contractile system, the fraction of myosin bound to actin increased sigmoidally indicative of cooperative binding as myosin concentration increases [46]. Finally, the rate of myosin II assembly into bipolar thick filaments was enhanced nearly 10-fold by the addition of actin filaments, but only in the presence of ATP [47]. In contrast, the addition of ADP plus actin inhibited thick filament assembly. We now understand that this rate enhancement is most likely due to cluster formation of the myosin II heads on the actin due to cooperative binding, which in turn increases the proximity of the myosin II tails, promoting thick filament assembly [37].

Similar hetero-cooperativity may exist between myosin II and cortexillin, which could lead to formation of clusters containing both proteins, as was observed *in silico* [37]. Thus, these proteins form the core of a mechanoresponsive contractile unit, where myosin II is the force-generating element and cortexillin I anchors the actin network, and helps propagate forces through this network. In contrast, α -actinin, which is also an actin bundling protein found at the cleavage furrow, only accumulates in response to mechanical stress in *Dictyostelium myoII* null cells [14]. The polar crosslinkers also exhibit antagonistic behavior with myosin II. Myosin II accumulates at ~2-fold lower pressures in interphase cells depleted of polar crosslinker dynacortin or the small GTPase *racE*, which regulates many polar crosslinkers [14]. Thus, force-sharing between myosin II and actin crosslinkers defines the cellular mechanical landscape, and determines cleavage furrow contractility during cytokinesis. Due to its importance in ensuring cytokinesis fidelity, cellular mechanosensing is highly regulated through feedback. Some such regulatory mechanisms are discussed in the section below.

6. Feedback regulation of cytokinesis and mechanosensing

In engineering, feedback loops have long been appreciated as a means of ensuring robustness [48]. Mechanosensory feedback during cytokinesis has a similar effect [28]. During cytokinesis, signals from the mitotic spindle initiate symmetry breaking and recruitment of cleavage furrow proteins to the cell equator. Subsequently, mechanical feedback and cooperativity between myosin II and cortexillin I control the amount of protein and contractility at the furrow. Furthermore, two cortexillin I-binding proteins, IQGAP1 and IQGAP2, help regulate this mechanoresponsive system [13]. In the absence of IQGAP2, myosin II and cortexillin I fail to accumulate in response to applied stress due to inhibition by IQGAP1. However, a double mutant lacking both IQGAPs is highly mechanoresponsive, indicating that the IQGAPs are not required for mechanoresponsiveness, and that they only play regulatory roles. Further, IQGAP2 transduces the readout from the mechanosensor back to the spindle signaling proteins. IQGAP2 is required for directing mechanical stress-dependent accumulation of the mitotic kinesin-like protein (MKLP) Kif12 and the chromosome passenger complex protein INCENP to the cell cortex [13]. Overall, these mechanical feedback loops spatially and temporally tune myosin II accumulation and contractility, and are structured similar to control systems ubiquitous in engineering (Fig. 3).

In addition to the equatorial mechanosensory control system, global cellular mechanics also contribute to cytokinesis fidelity. The small GTPase *racE* is a global regulator of cortical mechanics promoting resistive stresses [49], and is an upstream activator of many polar actin crosslinkers including dynacortin and coronin [3,12,50]. The overexpression of polar crosslinkers inhibits myosin II mechanoresponsiveness, while the absence of *racE* or dynacortin makes myosin II more responsive. During cytokinesis, the equatorial mechanoresponsive unit (myosin II and cortexillin I) and the polar resistive module (*racE* and other actin crosslinkers) exhibit inverse concentration gradients, promoting furrow ingression. Though the equatorial and polar modules have complementary roles during cytokinesis, crosstalk occurs between them. *RacE* also acts upstream of the regulatory protein 14-3-3, which is enriched in the polar cortex where it regulates cortical tension and steady state microtubule length [51]. 14-3-3 then binds to the myosin II heavy chain and promotes myosin II bipolar thick filament turnover at the furrow [51]. Collectively, these mechanisms demonstrate the interplay between polar and equatorial modules in regulating myosin II contractility, and their importance in maintaining cell shape during cytokinesis [4].

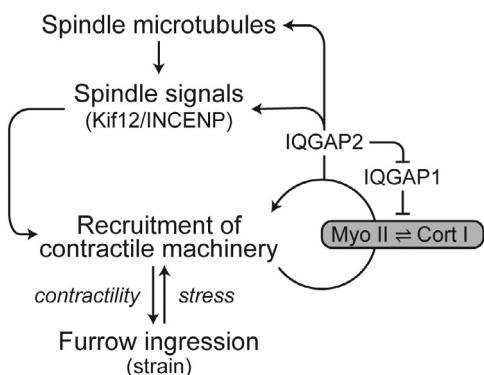

Fig. 3. A mechanosensory control system regulates myosin II accumulation and contractility at the cleavage furrow. Signals from the mitotic spindle and mechanical stress recruit contractile machinery. Myosin II and cortexillin I form the core of this mechanosensory system. IQGAP-proteins regulate mechanosensitive accumulation of myosin II and cortexillin I. A feedback loop to spindle signaling proteins through IQGAP2 provides additional amplification of contractility at the furrow. Deletion of any of the factors of this feedback system causes increased cytokinesis failure, including daughter cell symmetry defects, which is indicative of each protein contributing to the robustness of the cell division system.

Though the roles of myosin II and many actin crosslinkers in cytokinesis and contractility have been examined carefully, the molecular mechanisms for the recruitment and retention of these proteins is not fully elucidated. For example, a myosin II mutant lacking the motor domain (headless myosin) can partially accumulate in the furrow region, though it does not incorporate into the cortex, highlighting the importance of the motor-actin interactions for integrating myosin II into the cortex [52]. However, the fact that the headless myosin can enrich in the furrow cytoplasm indicates that there are still more contributing mechanisms. Emphasizing this, a genetic selection has identified novel roles for many proteins, including RMD1 (regulator of microtubule dynamics-1) and mmsdh (methylmalonate semialdehyde dehydrogenase), in rescuing defects in myosin II BTF assembly and furrow enrichment [38]. Thus, multiple parallel pathways regulate myosin II furrow localization and cellular contractility, thereby providing robustness to the cellular cytokinesis machinery.

7. Cytokinesis regulation in other systems

In this article, we have mostly focused on the regulatory mechanisms for cytokinesis and cell shape control in the amoeba *Dictyostelium*. However, these concepts are not specific to one organism or process, but can be extended to a wide variety of organisms and cellular processes. The genetic simplicity and biochemical and mechanical amenability of *Dictyostelium* make it a powerful model to obtain mechanistic insights into cytokinesis regulation. Most proteins mentioned here have direct homologs, and their behavior has been replicated in other species. For example, myosin II is the major driver of contractility in most non-muscle cells, and is responsive to mechanical stress in other cell types including *Drosophila* S2 cells [5] and human hematopoietic stem cells [53]. In budding yeast, myo1 (the myosin II homolog) is immobilized during cytokinesis [54], similar to the stabilization of cleavage furrow proteins in *Dictyostelium*. Additionally, during mammalian cytokinesis, if the cortex becomes destabilized, the myosin II network can undergo fluctuating assembly and disassembly, resulting in a destabilized furrow and oscillating contractions across the cell and further highlighting the feedback control in contractile network [55]. Further, F-actin is not required for retaining myosin II at the equator once the ring-like structure has formed in fission yeast [56].

These results suggest that the cell cortex is highly mechanosensitive across species, and its ability to respond to mechanical forces is critical to ensuring robust cytokinesis. Perturbations to actomyosin contractility and cellular mechanics lead to cytokinesis defects in several species including vertebrates, nematodes and yeast [2,25,27]. In vertebrates, myosin II depletion results in highly multinucleated cells, and this defect can be restored by exogenous expression of any of the three myosin II isoforms [57]. Further, the ability of myosin II to generate tension in the network, rather than its ability to translocate actin filaments, is required for cytokinesis as shown using a myosin II mutant with no motility and an extremely long actin-attachment time [58,59]. Similarly, in *Dictyostelium*, a myosin II mutant for which the Mg²⁺-ATPase activity is uncoupled from its power stroke responds to mechanical stress like wild type myosin II [17].

In addition to regulation of actomyosin contractility [60], feedback is also important in various other aspects of cell division. For example, the dynamic recruitment of the CPC to the central spindle is tightly controlled through many feedback loops involving Aurora B kinase [61,62]. In fission yeast, the contractile network assembly is triggered by the septation initiation network (SIN) through the activation of Rho1 GTPase. Recent evidence has shown that Rho1 can also affect upstream regulators of SIN, thereby providing feedback to control actomyosin assembly and furrow ingression [63]. Thus, different systems have evolved intricate methods to ensure that cytokinesis proceeds with high fidelity.

8. Concluding remarks

Biological systems are designed to survive in a variety of scenarios. Key to their survival is the ability of cells to divide robustly under challenging conditions. Thus, organisms have developed sophisticated machinery that, at first glance, appears to be overbuilt. However, these complex networks are needed to ensure robust tight spatial and temporal regulation of essential components. During cell division, many biochemical and mechanical feedback loops collectively serve as checkpoints that allow for the detection and correction of defects that could be deleterious. Here, we have detailed the elaborate mechanisms that tune the assembly and dynamics of the actomyosin contractile unit at the cleavage furrow in dividing cells. Cooperativity and force-sharing between molecular motors (myosin II) and structural proteins (actin crosslinkers) form the basis of this mechanically tunable system [14]. Hence, Rappaport appropriately concluded that cytokinesis is indeed a complex shape change process that is over-built and hard to fail.
